

1) (10 pts) DSN (Binary Trees)

The goal of a function named *legacyCount()* is to take the root of a binary tree (*root*) and return the number of nodes that contain a value greater than at least one of their ancestors. For example, this function would return **4** for the following tree, since **60** is greater than both of its ancestors (3 and 14), **40** is greater than two of its ancestors (3 and 14) (even though 40 isn't greater than its parent!), **28** is greater than both of its ancestors (9 and 14), and **2** is greater than one of its ancestors (1).

Our node struct is as follows:

```
typedef struct node {
    int data;
    struct node *left;
    struct node *right;
} node;
```

To make the code work, *legacyCount()* is a wrapper function for a recursive function called *legacyHelper()*. Included below is the code for *legacyCount()* as well as the function signature for *legacyHelper()*. Write all of the code for the *legacyHelper()* function. Note: If *root* is NULL, you should return 0.

```
int legacyCount(node *root) {
    if (root == NULL) return 0;
    return legacyHelper(root->left, root->data) +
           legacyHelper(root->right, root->data);
}

int legacyHelper(node* root, int minAncestor) {
```

```
}
```
